A Logic for Non-Terminating Golog Programs

Jens Claßen and Gerhard Lakemeyer

Abstract

Typical Golog programs for robot control are non-terminating. Analyzing such programs so far requires meta-theoretic arguments involving complex fix-point constructions. In this paper we propose a logic based on the situation calculus variant \(\mathcal{ES}\), which includes elements from branching time, dynamic and process logics and where the meaning of programs is modelled as possibly infinite sequences of actions. We show how properties of non-terminating programs can be formulated in the logic and, for a subset of it, how existing ideas from symbolic model checking in temporal logic can be applied to automatically verify program properties.

Introduction

The action language Golog (Levesque et al. 1997), which is based on the situation calculus (McCarthy & Hayes 1969; Reiter 2001), has already been successfully applied to the control of autonomous agents and robots. Usually, such robots fulfill open-ended, non-terminating tasks. Before deploying a control program and actually executing it in the real world, it is often desirable to verify that certain requirements are met. Typical examples are safety, liveness and fairness conditions.

As a simple example (adapted from (De Giacomo, Ternovska and Reiter 1997)) that we will refer to throughout the paper, consider a mobile robot working in an office environment whose task is to serve coffee to people on request. When a new request arrives before the current one has been served, it is stored in a queue. A possible control program for such a robot might look like this:

\[
\text{loop : if } \neg\text{Empty(queue)} \quad \rightarrow\text{selectRequest(p);} \quad \text{pickupCoffee; bringCoffee(p)} \quad \text{else wait}
\]

Here the robot performs an infinite loop. In each iteration, when the queue is currently not empty, the next request (which comes from person p) is selected to be served, which means that the coffee has to be obtained at the coffee machine and brought to p’s office. If there are no requests at all, the robot waits for a short period. Requests, which constitute exogenous actions in this scenario, may arrive at any time. Examples for program properties one may want to verify are: “Every request will eventually be served by the robot;” and “it is possible that no request is ever served.”

Popular means for expressing such properties are temporal logics, in particular \(\mathcal{LTL}, \mathcal{CTL}\) and \(\mathcal{CTL}^*\). (Emerson 1990). For these logics, there exists a variety of algorithms (Clarke, Grumberg, & Peled 1999) and tools (Cimatti et al. 2002; Holzmann 2003) for checking whether a certain formula is satisfied in a given finite model of a concurrent system. These model checking methods have been successfully applied in practice for the verification of circuit design and communication protocols.

For computational complexity reasons, temporal logics are typically restricted to the propositional case. A Golog domain designer who wants to verify a certain control program is now confronted with the problem that the program and the corresponding background theory has to be abstracted and translated in order to be compatible with the temporal logic and the model checking tool that is to be used. Doing this manually is error-prone. On the other hand, an automated translation or embedding would certainly mean a loss of some of the expressive capabilities, such as first-order quantification. These are however considered desirable features that one would rather not give up, but are the reason why the language was chosen in the first place. It seems more preferable to be able to do the verification in the same formalism that is used for the specification and the actual control of the agent.

De Giacomo, Ternovska and Reiter (1997) show how both the meaning of programs and the properties to be verified can be expressed using fix-point constructions in the style of the \(\mu\)-calculus, which is known to constitute a superset of the linear and branching time temporal logics named above. Fix points are expressed by means of formulas of second-order logic and one then has to do a manual, meta-theoretic proof of the desired property. There are automated tools that are capable of determining fix points of inductive definitions (Pelov & Ternovska 2005), but they are again often limited to the propositional case.

In this paper, we present a new logic, called \(\mathcal{ES}\), to express and reason about programs and their properties. It is based on the situation calculus variant \(\mathcal{ES}\) (Lakemeyer & Levesque 2004) which makes certain restrictions that ease theoretical treatments, but does not yield a loss of expres-
siveness compared to the original situation calculus (Lakemeyer & Levesque 2005). In the non-epistemic case that we will consider here, one of these restrictions is that it assumes a fixed universe of discourse, which allows to treat quantification substitutionally. Another one is that future situations can only be referred to by means of the modal operators \([t]\) (“after the action \(t\)”) and \(\Box\) (“in all future situations”).

Here we propose two extensions of the language. For one, we will allow not only atomic actions, but arbitrary Golog programs as arguments of the \([\cdot]\) operator. The formula \([\delta]\alpha\) then means that after executing the program \(\delta\), formula \(\alpha\) will hold. Programs are composed of atomic actions and tests by means of constructors for non-deterministic choice, finite and infinite iteration, sequential composition and concurrency. In particular, this part of the language resembles dynamic logic (Harel, Kozen, & Tiuryn 2000), though our formalisms is more expressive in terms of modeling arbitrary atomic actions and using first-order quantification. The meaning of programs is defined inside the logic’s semantics. We show that in case of terminating programs it is equivalent to the definition of Golog programs in (Lakemeyer & Levesque 2005).

For another, we want to go beyond reasoning about what holds after executing a program (which is especially useless in case of non-terminating processes) and consider properties which hold during its execution. For this purpose, we introduce formulas of the form \([\delta]\alpha\) which expresses that \(\alpha\) holds for all possible runs of program \(\delta\), where \(\alpha\) may contain operators like “until”, “eventually” or “globally” known from temporal logics. As an example, assume that \(\delta\) refers to the above program. Then

\[\Box\alpha(G(requestCoffee(p)) \supset FOcc(selectRequest(p)))\]

states that for all possible executions of \(\delta\), it is always (\(G\)) the case that when a requestCoffee occurs by some person \(p\), then eventually (\(F\)) that request will be selected to be served.

For the CTL-like fragment of the language we also provide an automated method to verify program properties. Roughly, for a given program, we first construct what we call a characteristic graph, where nodes represent program states and edges are labelled with actions and conditions, under which these action can be taken. Conditions involving temporal operators like “until” are then tested by computing fix points w.r.t these graphs, using methods from model checking. An adaptation further allows to also check postconditions of terminating programs. Since first-order reasoning is involved in each case, only correctness can be guaranteed but not termination.

The rest of the paper is organized as follows. In the next section we introduce the logic \(\ESG\) and show how it relates to the original \(\ES\) and Golog. Then we focus on the verification of properties of non-terminating and terminating programs with underlying basic action theories. After discussing related work we conclude.

**The Logic \(\ESG\)**

The language is a second-order modal dialect with equality and sorts of type object, action. It includes countably infinitely many standard names for each sort. Also included are both fluent and rigid predicate and function symbols, as well as rigid and fluent second-order variables. Flucts vary as the result of actions, but rigid do not. We assume that the fluents include unary predicates \(\text{Poss}, \text{Occ},\) and \(\text{Exo}\), whose argument is of type action.

The logical connectives are \(\land, \neg, \forall, \lor\), together with these modal operators: \(X, U, [\delta],\) and \(\langle \delta \rangle\), where \(\delta\) is a program defined below. Other connectives like \(\lor, \supset, \land, \exists,\) and \(\forall\) are used as the usual abbreviations.

**Terms and formulas**

Terms are formed in the usual way. Note that standard names syntactically are treated like ordinary constants. By a *primitive term* we mean one of the form \(h(n_1, \ldots, n_k)\) where \(h\) is a (fluent or rigid) function symbol and all of the \(n_i\) are standard names.

Formulas are divided into two classes, situation and trace formulas. As their names suggest, situation formulas express properties that hold in a certain situation, while trace formulas describe properties of finite and infinite action sequences. The set of all formulas is defined to be the least set such that for the situation formulas:

1. If \(t_1, \ldots, t_k\) are terms, and \(H\) is a \(k\)-ary predicate symbol then \(H(t_1, \ldots, t_k)\) is an (atomic) situation formula;
2. If \(t_1, \ldots, t_k\) are terms, and \(V\) is a \(k\)-ary second-order variable, then \(V(t_1, \ldots, t_k)\) is an (atomic) situation formula;
3. If \(t_1\) and \(t_2\) are terms, then \((t_1 = t_2)\) is a sit. formula;
4. If \(\delta\) is a program, \(\alpha\) is a situation formula and \(\phi\) is a trace formula, then \([\delta]\alpha\) and \([\delta]\phi\) are situation formulas;
5. If \(\alpha\) and \(\beta\) are situation formulas, \(v\) is a first-order variable, and \(V\) is a second-order variable, then the following are also situation formulas: \((\alpha \land \beta), \neg \alpha, \forall v. \alpha, \forall V. \alpha\).

The trace formulas are further defined as follows:

1. Every situation formula is a trace formula;
2. If \(\phi\) and \(\psi\) are trace formulas, \(v\) is a first-order variable and \(V\) is a second-order variable, then \(\phi \land \psi\), \(\neg \phi\), \(\forall v. \phi\), \(\forall V. \phi\), \(X\phi\) and \(\phi \ U \psi\) are also trace formulas.

We read \([\delta]\) as “\(\alpha\) holds after all possible executions of \(\delta\)”, \([\delta]\phi\) as “\(\phi\) holds for all possible executions of \(\delta\)”, \(Occ(t)\) as “\(t\) was the last action”, \(X\phi\) as “\(\phi\) holds after the next action” and \(\phi \ U \psi\) as “\(\phi\) will hold until \(\psi\) holds”. To obtain the duals of \([\delta]\alpha\) and \([\delta]\alpha\), we let \([\delta]\alpha\) stand for \(\neg[\delta]\neg\alpha\) and \([\delta]\alpha\) for \(\neg[\delta]\neg\alpha\).

Formulas without free variables are called sentences. A primitive sentence is a predicate whose arguments are standard names. We call a formula without \([\delta]\), \([\delta]\), \(\text{Poss}, \text{Exo}\) and \(\text{Occ}\) a fluent formula. A formula that does not contain \([\delta]\) and where at most \([t]\) appear where the argument \(t\) is an atomic action is called a bounded formula.

**Programs**

Programs are composed according to the following grammar:

\[\delta := t \mid \varphi \mid ([\delta_1; \delta_2] \mid (\delta_1|\delta_2) \mid \pi x.\delta \mid (\delta_1|\delta_2) \mid \delta^\ast)\]

Here, \(t\) is any (not necessarily ground) term of sort action and \(\varphi\) can be any situation formula of the full. In the presented order, the constructs mean a primitive action, a test, sequence of programs, nondeterministic choice between
programs, nondeterministic choice of argument, concurrent execution of programs, and nondeterministic iteration. We remark that, except for procedures, the program constructs essentially correspond to those of ConGolog (De Giacomo, Lespérance, & Levesque 2000). Further control structures can be introduced as abbreviations:

\[
\begin{align*}
\text{if } \varphi \text{ then } & \delta_1 \text{ else } \delta_2 \text{ endIf} \quad \text{def} = \varphi?\cdot \delta_1 | \neg \varphi?\cdot \delta_2 \\
\text{while } \varphi \text{ do } & \delta \text{ endWhile} \quad \text{def} = (\varphi?)\cdot \delta; \neg \varphi?
\end{align*}
\]

\[\text{loop } \delta \quad \text{def} = \text{while } \top \text{ do } \delta \text{ endWhile}\]

For the purpose of this paper, the loop construct is particularly important; we will also abbreviate it as \(\delta^\omega\).

The idea of co-referring standard names is extended to arbitrary ground terms as follows. Given a variable-free term including the empty sequence \(\epsilon\), any finite or infinite sequence of standard names of sort action, \(\{H\}\), and variable map \(\alpha\), we finally understand \(\Box\alpha\) as an abbreviation for \(\forall \alpha\).

The Semantics
To determine the truth of a sentence, we need a world \(w\) which determines the truth values of primitive sentences and co-referring standard names for primitive terms after any sequence of actions. Formally:

A world \(w \in W\) is any function from the primitive sentences and \(\mathcal{Z}\) to \(\{0,1\}\), and from the primitive terms and \(\mathcal{Z}\) to \(\mathcal{N}\) (preserving sorts), and satisfying the rigidity constraint: if \(r\) is a rigid function or predicate symbol, then \(w[r(n_1, \ldots, n_k),z] = w[r(n_1, \ldots, n_k),z']\) for all \(z, z' \in \mathcal{Z}\).

Here, \(\mathcal{N}\) denotes the set of all standard names and \(\mathcal{Z}\) the set of all finite sequences of standard names of sort action, including the empty sequence \(\epsilon\).

The idea of co-referring standard names is extended to arbitrary ground terms as follows. Given a variable-free term \(t\), a world \(w\), and an action sequence \(z\), we define \(|t|^z_w\) (read: the co-referring standard name for \(t\) given \(w\) and \(z\)) by:

1. If \(t \in \mathcal{N}\), then \(|t|^z_w = t\).
2. \(|h(t_1, \ldots, t_k)|^z_w = w[h(n_1, \ldots, n_k),z]\), where \(n_i = |t_i|^z_w\).

To interpret formulas with free variables, we proceed as follows. First-order variables are handled substitutionally using the standard names. To handle the quantification over second-order variables, we use second-order variable maps defined as below:

The second-order primitives are formulas of the form \(V(n_1, \ldots, n_k)\) where \(V\) is a fluent or rigid second-order variable and all of the \(n_i\) are standard names. A variable map \(u\) is a function from second-order primitives and \(\mathcal{Z}\) to \(\{0,1\}\), satisfying the rigidity constraint: if \(Q\) is a rigid second-order variable, then for all \(z\) and \(z'\) in \(\mathcal{Z}\), \(u[Q(n_1, \ldots, n_k),z] = u[Q(n_1, \ldots, n_k),z']\).

\[\text{Let } u \text{ and } u' \text{ be variable maps, and let } V \text{ be a second-order variable; we write } u \sim_V u' \text{ to mean that } u \text{ and } u' \text{ agree except perhaps on the second-order primitives involving } V.\]

Now given \(w \in W\), we define \(w \models \alpha\) for situation formulas \(\alpha = w, \{\}, u = \alpha\) for all variable maps \(u\), where for any sequence \(z \in \mathcal{Z}\), and variable map \(u\):

1. \(w, z, u = H(t_1, \ldots, t_k) \iff w[H(n_1, \ldots, n_k),z] = 1, \text{ where } n_i = |t_i|^z_w;\)
2. \(w, z, u = V(t_1, \ldots, t_k) \iff u[V(n_1, \ldots, n_k),z] = 1, \text{ where } n_i = |t_i|^z_w;\)
3. \(w, z, u = (t_1 = t_2) \iff n_1 \text{ and } n_2 \text{ are identical, where } n_i = |t_i|^z_w;\)
4. \(w, z, u = \text{Occ}(t) \iff \exists z' \cdot n, \text{ where } n = |t|^z_w;\)
5. \(w, z, u \models \alpha \land \beta \text{ iff } w, z, u \models \alpha \text{ and } w, z, u \models \beta;\)
6. \(w, z, u \models \neg \alpha \text{ iff } w, z, u \not\models \alpha;\)
7. \(w, z, u \models \forall v. \alpha \text{ iff } w, z, u \models \alpha_n^v \text{ for all } n \in \mathcal{N}_v;\)
8. \(w, z, u \models \forall V. \alpha \text{ iff } w, z, u' \models \alpha \text{ for all } u' \sim_V u;\)
9. \(w, z, u \models [\delta]\phi \text{ iff for all } \tau \in [\delta]^w(z), w, z, \tau, u \models \phi;\)
10. \(w, z, u \models [\delta][\alpha] \text{ iff for all finite } z' \in [\delta]^w(z), w, z \cdot z', u \models \alpha.\)

\(\mathcal{N}_v\) refers to the set of standard names of the same sort as \(v\). \(\alpha_n^v\) means \(\alpha\) with every free occurrence of \(v\) replaced by \(n\).

\[\text{Rule 10 only requires that } \alpha \text{ holds after all finite sequences for } [\delta][\alpha] \text{ to be true. In particular this implies that any formula is vacuously true "after" the execution of a non-terminating program } \delta^\omega.\]

On the other hand, in rule 9, the trace formula \(\phi\) must hold for any trace \(\tau\), be it finite or not. The truth of trace formulas is given by:

1. \(w, z, \tau, u \models \alpha\iff w, z, u \models \alpha, \text{ where } \alpha \text{ is a situation formula;}\)
2. \(w, z, \tau, u \models \phi \land \psi \text{ iff } w, z, \tau, u \models \phi \text{ and } w, z, \tau, u \models \psi;\)
3. \(w, z, \tau, u \models \neg \phi \text{ iff } w, z, \tau, u \not\models \phi;\)
4. \(w, z, \tau, u \models \forall v. \phi \text{ iff } w, z, \tau, u \models \phi_n^v \text{ for all } n \in \mathcal{N}_v;\)
5. \(w, z, \tau, u \models \forall V. \phi \text{ iff } w, z, \tau, u' \models \phi \text{ for all } u' \sim_V u;\)
6. \(w, z, \tau, u \models X \phi \text{ iff } \tau = \tau' \text{ and } w, z \cdot n, \tau', u \models \phi;\)
7. \(w, z, \tau, u \models U \psi \text{ iff there is } z' \text{ such that } \tau = z' \cdot \tau' \text{ and } w, z \cdot z', \tau', u \models \psi \text{ and for all } z'' \not= z' \text{ with } z'' \cdot z''' \cdot \tau'' \models \phi.\)

When \(\Sigma\) is a set of sentences and \(\alpha\) is a sentence, we write \(\Sigma \models \alpha\) (read: \(\Sigma\) logically entails \(\alpha\)) to mean that for every \(w\), if \(w \models \alpha'\) for every \(\alpha' \in \Sigma\), then \(w \models \alpha\). Finally, we write \(\models \alpha\) (read: \(\alpha\) is valid) to mean \(\{\} \models \alpha\). As a notational convention, we will in the following always use (possibly with sub- or superscripts) \(z\) for finite sequences, \(\pi\) for infinite ones and \(\tau\) for arbitrary traces.
The Meaning of Programs  The program semantics we present here is an adaptation of the single step semantics of (De Giacomo, Lepérance, & Levesque 2000). A key difference is that we do not define the meaning of programs axiomatically, but inside the logic. We also treat tests differently in that we do not view them as transitions, but rather as conditions under which a transition (which is always physical action in our framework) may be taken or under which the run of a program may terminate.

A central concept is that of a configuration, which we denote as a pair $(\delta, z)$, where $\delta$ is a program (intuitively what remains to be executed) and $z$ a sequence of actions (that have been already performed). Program configurations can be final, which means that the run may successfully terminate in that particular situation, or they can make certain transitions to other configurations, each of which involves performing some physical action.

Formally, the set of final configurations $F^{w,u}$ is the smallest set such that for all $\delta, \delta_1, \delta_2$, situation formulas $\varphi$ and finite $z$:

1. $(\varphi, z) \in F^{w,u}$ if $w, u, z \models \varphi$;
2. $(\delta_1; \delta_2, z) \in F^{w,u}$ if $(\delta_1, z) \in F^{w,u}$ and $(\delta_2, z) \in F^{w,u}$;
3. $(\delta_1)_{\delta_2, z} \in F^{w,u}$ if $(\delta_1, z) \in F^{w,u}$ or $(\delta_2, z) \in F^{w,u}$;
4. $(\pi x. \delta, z) \in F^{w,u}$ if $(\delta_{n, z}) \in F^{w,u}$ for some $n \in N_z$;
5. $(\delta, z) \in F^{w,u}$;
6. $(\delta, \delta_2, z) \in F^{w,u}$ if $(\delta_1, z) \in F^{w,u}$ and $(\delta_2, z) \in F^{w,u}$.

Thus, a configuration $(\varphi, z)$ whose remaining program is a test is final wrt $w$ and $u$ if the formula $\varphi$ holds at $w, z, u$.

From the above it also follows that $(t, z) \not\in F^{w,u}$ for atomic $t$, i.e. if some action $t$ remains to be done, the configuration cannot be final. Further, sequences are only final when the involved subprograms are both final etc. The transition relation among configurations is given as follows:

1. $(t, z) \rightarrow (nil, z \cdot n)$ if $n = |t|_z^w$;
2. $(\delta_1; \delta_2, z) \rightarrow (\gamma; \delta_2, z \cdot n)$ if $(\delta_1, z) \rightarrow (\gamma, z \cdot n)$;
3. $(\delta_1; \delta_2, z) \rightarrow (\delta', z \cdot n)$ if $(\delta_1, z) \in F^{w,u}$ and $(\delta_2, z) \rightarrow (\delta', z \cdot n)$;
4. $(\delta_1)_{\delta_2, z} \rightarrow (\delta', z \cdot n)$ if $(\delta_1, z) \rightarrow (\delta', z \cdot n)$ or $(\delta_2, z) \rightarrow (\delta', z \cdot n)$;
5. $(\pi x. \delta, z) \rightarrow (\delta', z \cdot n)$ if $(\delta_1, z) \rightarrow (\delta', z \cdot n)$ or $(\delta_2, z) \rightarrow (\delta', z \cdot n)$;
6. $(\delta, z) \rightarrow (\gamma; \delta', z \cdot n)$ if $(\delta, z) \rightarrow (\gamma, z \cdot n)$;
7. $(\delta_1; \delta_2, z) \rightarrow (\delta'_{\delta_2, z} \cdot n)$ if $(\delta_1, z) \rightarrow (\delta', z \cdot n)$;
8. $(\delta_1)_{\delta_2, z} \rightarrow (\delta_1)_{\delta', z \cdot n}$ if $(\delta_2, z) \rightarrow (\delta', z \cdot n)$.

Above, nil denotes the empty program and should be read as an abbreviation for $\top$. $(t, z)$ may therefore successfully terminate after performing physical action $n$, the latter being the action standard name by which $t$ is interpreted in $w$ at $z$. A sequence of programs can either make a transition in the first subprogram or a transition in the second subprogram, provided that the first one is final etc.

We can now define the set $[\delta]^{w}_u(z)$ of execution traces of a program $\delta$, given $w, u, z$. In general this set may contain both finite and infinite sequences of action standard names. If $\rightarrow_\delta$ is the reflexive transitive closure of $\rightarrow$, $[\delta]^{w}_u(z)$ is

$$\{ z' \mid (\delta, z) \rightarrow_\delta (\delta', z \cdot z') \text{ and } (\delta', z \cdot z') \in F^{w,u} \} \cup \{ \pi \mid \text{for all } z' \in \text{Pre}(\pi), (\delta, z) \rightarrow_\delta (\delta', z \cdot z') \text{ and } (\delta', z \cdot z') \not\in F^{w,u} \},$$

where Pre($\pi$) is the set of all prefixes of $\pi$. A finite execution trace therefore is given by repeatedly following the transition relation and ending up in a terminating configuration; infinite runs never visit final configurations.

\section*{\ES is part of \ESG}  The language presented in the previous section is in fact a superset of the non-epistemic part of \ES as presented in (Lakemeyer & Levesque 2005):

\begin{theorem}
Let $\alpha$ be a sentence of \ES without epistemic operators. Then $\models_{\ES} \alpha \iff \models_{\ESG} \alpha$.
\end{theorem}

The theorem, which is proved in the appendix, essentially tells us that our $[\delta]$ operator, when restricted to atomic actions $t$, corresponds to Lakemeyer and Levesque’s $[t]$ operator. Furthermore our definition of $\Box \alpha$ as an abbreviation for AG$\alpha$ correctly captures their semantics for this construct.

Lakemeyer and Levesque provide a macro-based definition of the semantics of terminating Golog programs which they prove to be equivalent to the one for the classical situation calculus:

\begin{definition}[The Do Semantics] Let $\alpha, \varphi$ be formulas and $\delta, \delta'$ be Golog programs.
1. $\Do(t, \alpha) \overset{\text{def}}{=} (\Poss(t) \land [t] \alpha)$;
2. $\Do(\varphi), \alpha \overset{\text{def}}{=} (\varphi \land \alpha)$;
3. $\Do(\delta; \delta', \alpha) \overset{\text{def}}{=} \Do(\delta, \Do(\delta', \alpha))$;
4. $\Do(\delta, \alpha) \overset{\text{def}}{=} \Do(\delta, \alpha) \lor \Do(\delta', \alpha)$;
5. $\Do(\pi x. \delta, \alpha) \overset{\text{def}}{=} \exists x. \Do(\delta, \alpha)$;
6. $\Do(\delta', \alpha) \overset{\text{def}}{=} \forall P. \square(\alpha \supset P) \land \Box(\Do(\delta, \supset P) \supset P)$.
\end{definition}

$\Do(\delta, \alpha)$ therefore can be expanded to a formula that states under which condition there is a successfully terminating execution of $\delta$ after which $\alpha$ will hold. In our logic, this fact can simply be expressed by a formula:

\begin{theorem}
Let $\delta$ be a program without $[]$ and $\alpha$ be a formula. Let $\delta'$ be $\delta$ with every atomic action $t$ replaced by $\Poss(t)\mid t$. Then $\models \Do(\delta, \alpha) \equiv (\delta')\alpha$.
\end{theorem}

\section*{Basic Action Theories and Regression}  Since we established the correspondence to the original \ES, we can make use of all results related to it, in particular concerning action theories and regression.
Basic Action Theories A basic action theory (BAT) is used to describe the specifics of a certain dynamic application domain. In ES and therefore also ES\(\Sigma\), they can be defined similar to Reiter-style BATs for the situation calculus. A set of sentences \(\Sigma\) is a basic action theory iff it only mentions the fluents in a given finite set \(\mathcal{F}\) and is of the form \(\Sigma = \Sigma_0 \cup \Sigma_{\text{pre}} \cup \Sigma_{\text{post}}\) where \(\Sigma_0\), the initial database, is a finite set of fluent sentences and \(\Sigma_{\text{pre}}\) is a precondition axiom of the form\(^3\) \(\Box \text{Poss}(a) \equiv \pi\), with \(\pi\) being a fluent formula whose only free variable is \(a\). \(\Sigma_{\text{post}}\) is a finite set of successor state axioms (SSAs)\(^4\)

\[
\Box [a] F(\vec{x}) \equiv \gamma_F \quad \text{and} \quad \Box [a] f(\vec{x}) = y \equiv \gamma_f
\]

for each relational fluent \(F \in \mathcal{F} \setminus \{\text{Poss}\}\) and each functional fluent \(f \in \mathcal{F}\), incorporating Reiter’s (2001) solution to the frame problem. \(\gamma_F\) has to be a fluent formula with free variables \(\vec{x}\), and \(\gamma_f\) one with free variables among \(\vec{x}\) and \(y\).

In the example case of the coffee delivery robot, \(\mathcal{F}\) consists of two fluents: \textit{HoldingCoffee} is relational and holds when the robot is currently holding coffee; \textit{queue} is functional and contains the current queue of coffee requests. Further we have five primitive actions: requestCoffee\((p)\) is the exogenous action (not under the robot’s control) of person \(p\) sending a request for coffee. selectRequest\((p)\) means the next request (which came from person \(p\)) from the queue is selected by the robot to be served. The robot can also go and get coffee from the coffee machine \(\text{pickupCoffee}\) and bring it to \(p\) \((\text{bringCoffee}(p))\). \textit{wait} finally means to do nothing for a while.

A possible initial database expresses that the robot initially is not holding coffee and the request queue is empty:

\(\Sigma_0 = \{\neg \text{HoldingCoffee}, \text{Empty}(\text{queue})\}\)

The preconditions \(\Sigma_{\text{pre}}\) are given by:

\[
\Box \text{Poss}(a) \equiv a = \text{wait} \lor \\
\exists p. a = \text{requestCoffee}(p) \land \neg \text{Full}(\text{queue}) \lor \\
\exists p. a = \text{selectRequest}(p) \land \text{IsFirst}(\text{queue}, p) \lor \\
\exists p. a = \text{bringCoffee}(p) \land \text{HoldingCoffee}
\]

Here, requestCoffee\((p)\) is only possible when the queue is not already full (assuming a fixed limit), \textit{pickupCoffee} only when the robot is not holding coffee etc. \(\Sigma_{\text{post}}\) finally contains the following successor state axioms:

\[
\Box [a] \text{HoldingCoffee} \equiv a = \text{pickupCoffee} \lor \\
\text{HoldingCoffee} \land \neg \exists p. a = \text{bringCoffee}(p),
\]

\[
\Box [a] \text{queue} = y \equiv \\
\exists p. a = \text{requestCoffee}(p) \land \text{enqueue}(\text{queue}, p, y) \lor \\
\exists p. a = \text{selectRequest}(p) \land \text{dequeue}(\text{queue}, p, y) \lor \\
\text{queue} = y \land \neg \exists p. (a = \text{requestCoffee}(p) \lor \\
a = \text{selectRequest}(p))
\]

For a queue with size limit \(k\), we use a simple encoding that represents the queue’s state by a term of the form \(\text{list}(p_1, \ldots, p_k)\), where empty positions are represented by having \(p_i = e\), \(e\) being a distinguished standard name. Above we made use of these abbreviations:

\[
\text{IsFirst}(q, p) \equiv (p \neq e) \land \\
\exists p_2 \ldots \exists p_k. q = \text{list}(p, p_2, \ldots, p_k),
\]

\[
\text{Empty}(q) \equiv q = \text{list}(e, \ldots, e),
\]

\[
\text{Full}(q) \equiv \exists x_1 \ldots \exists x_k. \land_{i=1}^k (x_i \neq e) \land \\
q = \text{list}(x_1, \ldots, x_k),
\]

\[
\text{Enqueue}(q, p, q_n) \equiv (p \neq e) \land \\
\forall_{i=0}^{k-1} \exists x_i. \land_{j=1}^i (x_i \neq e) \land \\
q_o = \text{list}(x_1, \ldots, x_i, e, \ldots, e) \land \\
q_n = \text{list}(x_1, \ldots, x_i, p, e, \ldots, e),
\]

\[
\text{Dequeue}(q, p, q_n) \equiv (p \neq e) \land \exists x_2 \ldots \exists x_k. \land \\
q_o = \text{list}(p, x_2, \ldots, x_k) \land \\
q_n = \text{list}(x_2, \ldots, x_{k-1}, e).
\]

Exogenous Actions To model actions that are not under the agent’s control, we include an additional axiom \(\Sigma_{\text{exo}}\) in the BAT. It has the form \(\Box \text{Exo}(a) \equiv \chi\), where \(\chi\) is a fluent formula whose only free variable is \(a\). It defines the necessary and sufficient conditions under which \(a\) is exogenous. In case of the coffee delivery robot, \(\chi\) is \(\exists p. a = \text{requestCoffee}(p)\). We then have a process \(\delta_{\text{exo}} = (\pi.a.\text{Exo}(a)?;}\) that constantly executes exogenous actions and use \((\delta_{\text{ctrl}}||\delta_{\text{exo}})\) instead of the actual control program \(\delta_{\text{ctrl}}\).

Regression For such BATs and formulas that only contain \(t\) constructs for atomic actions \(t\), (Lakemeyer & Levesque 2004) introduce an ES equivalent of Reiter’s regression operator. The idea behind regression is that whenever we encounter a subformula of the form \(\Box t F(\vec{x})\), we may substitute it by \(\gamma_F\), the right-hand side of the successor state axiom of \(F\). This is sound in the sense that the axiom defines the two expressions to be equivalent. The result of the substitution will be true in exactly the same worlds satisfying the action theory \(\Sigma\) as the original one, but contains one less modal operator \(\Box\). Similarly, \(\Box \text{Occ}(t')\) is replaced by \(t = t'\) and \(\text{Poss}(t)\) and \(\text{Exo}(t)\) by the right-hand sides of the corresponding axiom. Iteratively applying such substitution steps, we end up with a fluent formula that describes exactly the conditions on the initial situation under which the original, non-static formula holds. We have an adapted version of Lakemeyer and Levesque’s regression theorem:

**Theorem 4** Let \(\Sigma\) be a BAT and let \(\alpha\) be a bounded sentence. Then \(R[\alpha]\), the regression of \(\alpha\), is a fluent sentence and \(\Sigma \models \alpha \iff \Sigma_0 \models R[\alpha]\).

Program Verification We now have everything in hand to reason about programs. Typically, the verification of a program \(\delta\), given a BAT \(\Sigma\), amounts to checking whether \(\Sigma \models (\neg)\langle\delta\rangle \varphi\) (for non-terminating \(\delta\)) and \(\Sigma \models (\neg)\langle\delta\rangle\alpha\) (for terminating \(\delta\)).
Verifying Non-Terminating Programs

As a motivation, consider again the example control program \( \delta_{\text{coffee}} \) that was presented in the introduction and let \( \delta \) in the following stand for \( (\delta_{\text{coffee}} \parallel \delta_{\text{EXO}}) \). Then indeed the BAT presented in the last section entails these two sentences:

\[
\begin{align*}
\langle \delta \rangle G \text{Occ}(\text{requestCoffee}(p)) & \supset F \text{Occ}(\text{selectRequest}(p)) \\
\langle \delta \rangle G \neg \exists p(\text{Occ}(\text{selectRequest}(p))) &
\end{align*}
\]

Both properties that we mentioned in the introduction therefore actually hold: whenever a request for coffee occurs, it will eventually be served and it might happen that no request is ever served. Because of the former, the latter can only happen when there are no requests at all.

Instead of proving such properties manually, automated verification is of course preferable. We will present an algorithm that can do so for a restricted \( \mathcal{CTL} \)-like subset of \( \mathcal{EG} \). More precisely, we say that \( \varphi \in \mathcal{EG}_{\mathcal{CTL}} \) if it is built according to the following grammar:

\[
\varphi ::= (t_1 = t_2) | F(t) | G(t) | \neg \varphi | \varphi \wedge \varphi | \exists x. \varphi | \langle \delta \rangle X \varphi | \langle \delta \rangle U \varphi | \langle \delta \rangle G \varphi
\]

As in \( \mathcal{CTL} \), only using existential path quantifiers is no real restriction, since the following equivalences are valid:

\[
\begin{align*}
\langle \delta \rangle X \varphi & \equiv \neg \langle \delta \rangle (X \neg \varphi) \\
\langle \delta \rangle G \varphi & \equiv \neg \langle \delta \rangle (U \neg \varphi) \\
\langle \delta \rangle (\phi U \psi) & \equiv \neg \langle \delta \rangle (\neg \psi U (\neg \phi \wedge \neg \psi)) \wedge \neg \langle \delta \rangle G \neg \psi
\end{align*}
\]

The second example property above is in \( \mathcal{EG}_{\mathcal{CTL}} \), while the first one is not. We further require that programs have the form \( \delta_1 \cdots \delta_k \), which is rather typical for non-terminating robot control programs and therefore not a rigorous restriction. The example \( \delta \) is of this form, including the part that encodes exogenous actions.

**Characteristic Graphs**

A central idea of our algorithm is that we encode the space of reachable program configurations by what we call a characteristic graph of a program. The nodes \( V \) in such a graph are tuples of the form \( \langle \delta', \phi \rangle \), which intuitively denote the remaining program of the current run and the condition under which execution may terminate there. The initial node is denoted by \( v_0 \). Edges in \( E \) are labeled with tuples \( x \vec{x} : t/\psi \), where \( x \vec{x} \) is a list of variables (if it is empty, we omit the leading \( \pi \)), \( t \) is an action term and \( \psi \) is a formula (which we omit when it is \( \top \)). Intuitively, this means when one wants to take action \( t \), one has to choose instantiations for the \( \vec{x} \) and \( \psi \) must hold.

The rather lengthy formal definition of characteristic graphs is presented in the appendix. To get an intuition, consider Figure 1, which depicts the characteristic graph for \( \delta_{\text{coffee}} \parallel \delta_{\text{EXO}} \), where

\[
\begin{align*}
v_0 & = (\delta_{\text{coffee}} \parallel \delta_{\text{EXO}}, \bot) \\
v_1 & = ((\text{pickupCoffee}; \text{bringCoffee}(p); \delta_{\text{coffee}}) \parallel \delta_{\text{EXO}}, \bot) \\
v_2 & = ((\text{bringCoffee}(p); \delta_{\text{coffee}}) \parallel \delta_{\text{EXO}}, \bot)
\end{align*}
\]

The fact that the program is non-terminating is reflected in the cyclic structure of the graph and the fact that the termination condition in each node is \( \bot \). In the initial node, depending on whether \( \text{Empty}(\text{queue}) \) holds or not, either \( \text{wait} \) or the \( \text{selectRequest} \) is the only applicable (non-exogenous) action. In any configuration, an exogenous action (here: an incoming request) may occur, hence the reflexive edges \( \pi : a/\text{Exo}(a) \) at each node. Note that the preconditions of actions are omitted here; the corresponding graph for the above \( \delta \) is obtained by simply adjoining the condition \( \phi \) in each transition \( \pi : t/\phi \) with \( \text{Poss}(t) \).

**The Algorithm**

To check a formula of \( \mathcal{EG}_{\mathcal{CTL}} \) against some BAT \( \Sigma \), we transform it as follows:

\[
\begin{align*}
C((t_1 = t_2)) & = (t_1 = t_2); \\
C(F(t)) & = F(t); \\
C(\varphi_1 \land \varphi_2) & = C[\varphi_1] \land C[\varphi_2]; \\
C(\neg \varphi) & = \neg C[\varphi]; \\
C[\langle \delta \rangle G \varphi] & = \text{CHECKEG}[\delta, \varphi]; \\
C[\langle \delta \rangle X \varphi] & = \text{CHECKX}[\delta, \varphi]; \\
C[\langle \delta \rangle U \varphi] & = \text{CHECKU}[\delta, \varphi].
\end{align*}
\]

In each of the cases with path quantifiers, we first determine the characteristic graph of \( \delta \). The procedures for these cases operate on sets of labels of the form \( \langle \nu, \psi \rangle \), where \( \nu = (\delta', \phi) \) is a node in the graph and \( \psi \) is a formula, which should be regarded as a representation for all the infinitely many configurations \( (\delta', z) \) where \( \psi \) holds. Let us first consider the procedure for “next”:

**Procedure 1** **CHECKX**[\( \delta, \varphi \)]

\[
X := \text{PRE}[\delta, \text{LABEL}[\delta, C[\varphi]]]; \\
\text{return } \text{INITLABEL}[\delta, X]
\]

\( \text{LABEL}[\delta, \alpha] \) means the set where all vertices of \( \delta \) are labelled only with \( \alpha \), i.e.

\[
\text{LABEL}(\langle V, E, v_0 \rangle, \alpha) = \{ \langle v, \alpha \rangle \mid v \in V \}.
\]

The preimage of a set of labels is determined by traversing the edges in \( \delta \) backwards and regressing the formula in the each label, conjoined with the transition condition:

\[
\begin{align*}
\text{PRE}(\langle V, E, v_0 \rangle, S) & = \\
& \{ \langle v', R[\exists x. \phi \land [t] \psi] \rangle \mid v' \stackrel{t/x}{\rightarrow} v \in E, \langle v, \psi \rangle \in S \}
\end{align*}
\]

Finally, given a set of labels, we need a function that extracts the information about the initial situation, following the convention that an empty disjunction is understood as \( \bot \):

\[
\text{INITLABEL}(\langle V, E, v_0 \rangle, S) = \bigvee \{ \psi \mid \langle v_0, \psi \rangle \in S \}
\]
Therefore, to check whether there is some trace such that \( \varphi \) holds at the next situation, we recursively transform \( \varphi \), label all nodes with the result and compute the corresponding preimage using regression. The labels that are then at the initial node encode the conditions under which there is a trace with the desired property.

The procedures for “until” and “always” are presented below. They transform the set of labels iteratively until it converges. In case of “until”, the idea is to start with \( C[\varphi] \) labels and in each iteration, go one transition backwards to a configuration where \( C[\varphi] \) must hold. Similarly, for “always”, we have an initial labelling with \( C[\varphi] \) and iteratively conjoin the labels from the last iteration with its preimage.

**Procedure 2** CheckEU[\( \delta, \varphi, \psi \)]

\[
X := \text{LABEL}[G_\delta, C[\varphi]]; \quad X_O := \text{LABEL}[G_\delta, T]; \\
\text{while } X \neq X_O \text{ do} \\
\quad X_O := X; \\
\quad X := X \cup \text{AND}(\text{LABEL}[G_\delta, C[\varphi]], \text{PRE}[G_\delta, X]); \\
\text{end while} \\
\text{return INITLABEL}[G, X]
\]

**Procedure 3** CheckEG[\( \delta, \varphi \)]

\[
X := \text{LABEL}[G_\delta, C[\varphi]]; \quad X_O := \text{LABEL}[G_\delta, \bot]; \\
\text{while } X \neq X_O \text{ do} \\
\quad X_O := X; \\
\quad X := \text{AND}(X, \text{PRE}[G_\delta, X]); \\
\text{end while} \\
\text{return INITLABEL}[G_\delta, X]
\]

The conjunction of two sets of labels is as expected:

\[
\text{AND}(S_1, S_2) = \{ \langle v, \psi_1 \rangle \mid \langle v, \psi_2 \rangle \in S_1, \langle v, \psi_2 \rangle \in S_2 \}
\]

The condition “\( X \neq X_O \)” is violated when each label \( \langle v, \psi \rangle \in X \) has a counterpart \( \langle v, \psi' \rangle \in X_O \) such that \( \Sigma_{UNA} \models \psi \equiv \psi' \), where \( \Sigma_{UNA} \) are unique names axioms for actions. Since we allow first-order quantification, such tests for equivalence are in general undecidable. In practice it is however often sufficient to do simple syntactical simplifications (e.g. replace \( \phi \land \phi \) by \( \phi \) in order to detect convergence, as we will later see in the example.

**Theorem 5** Let \( \varphi \in ES\overline{\text{TC}} \). If the computation of \( C[\varphi] \) wrt \( \Sigma \) terminates, it is a fluent formula and

\[
\Sigma \cup \Sigma_{UNA} \models \varphi \quad \text{iff} \quad \Sigma_0 \cup \Sigma_{UNA} \models C[\varphi].
\]

As a remark, our procedures CheckEU[\( \delta, \varphi, \psi \)] and CheckEG[\( \delta, \varphi \)] correspond to the iterative approximation of least and greatest fix points in Kleene’s constructive proof of the Tarski-Knaster Theorem, which guarantees that these fix points exist. Of course since our formalism allows infinite state spaces, they need not be finite like in propositional CTL, i.e. the computation is not guaranteed to terminate.

**Example** We can apply the algorithm in order to check \( \langle \delta \rangle G \exists p. \neg \text{Empty}(\text{queue}) \) against the example BAT, where \( \delta \) denotes \( \delta_{\text{coffee}} \mid \delta_{\text{coffee}} \) and we have a small queue of size \( k = 2 \). Let \( rC(p) \) stand for \( \text{requestCoffee}(p) \), \( sR(p) \) for \( \text{selectRequest}(p) \) and \( \psi \) for \( \neg \exists p. (\text{Occ}(sR(p))) \).

The initial set of labels in CheckEG[\( \delta, \psi \)] then is \( X = \{ \langle v_0, \psi \rangle, \langle v_1, \psi \rangle, \langle v_2, \psi \rangle \} \)

Starting the first iteration of the loop, we have to determine the preimage of the current \( X \). \( \text{PRE}[G_\delta, X] \) consists of seven different labels, three of those for \( v_0 \), corresponding to the edges leaving that node:

\[
\langle v_0, R[\exists a. \text{Exo}(a) \land \text{Poss}(a) \land [a]t] \rangle \\
\langle v_0, R[\exists p. \text{Empty}(\text{queue}) \land \text{Poss}(\text{wait}) \land [\text{wait}]t] \rangle \\
\langle v_0, R[\exists p. \neg \text{Empty}(\text{queue}) \land \text{Poss}(sR(p)) \land [sR(p)]t] \rangle
\]

When applying regression and using the unique names assumption for actions, we obtain:

\[
\langle v_0, \exists a. (rC(p) \land \neg \text{Full}(\text{queue}) \land \neg \exists p. (sR(p)) \rangle \\
\langle v_0, \text{Empty}(\text{queue}) \land \exists t \land \exists \neg \exists t \rangle \\
\langle v_0, \exists p. \neg \text{Empty}(\text{queue}) \land \neg \text{Empty}(\text{queue}) \land \exists \bot \rangle
\]

These can be further simplified to

\[
\langle v_0, \neg \text{Full}(\text{queue}) \rangle, \langle v_0, \text{Empty}(\text{queue}) \rangle, \langle v_0, \bot \rangle
\]

Using all seven labels in \( \text{PRE}[G_\delta, X] \), we can determine \( \text{AND}(X, \text{PRE}[G_\delta, X]) \), which contains

\[
\langle v_0, \psi \land \neg \text{Full}(\text{queue}) \rangle, \langle v_1, \psi \land \text{Empty}(\text{queue}) \rangle, \langle v_0, \psi \land \bot \rangle
\]

and four other labels. This set becomes the new \( X \). Iterating such steps, we will observe convergence after the fifth iteration, ending up with \( X \) consisting of

\[
\langle v_1, \psi \land \neg \text{HoldingCoffee} \land \text{Empty}(\text{queue}) \rangle \\
\langle v_2, \psi \land \text{HoldingCoffee} \land \text{Empty}(\text{queue}) \rangle
\]

Therefore, \( C(\langle \delta \rangle G \psi) = \psi \land \text{Empty}(\text{queue}) \), which is clearly entailed by \( \Sigma_0 \cup \Sigma_{UNA} \). The result is also intuitively clear: A trace without \( sR(P) \) is possible just in case no \( sR(p) \) has yet occurred and there are no initial requests in the queue that have to be served.

The example also nicely demonstrates that for the convergence of our method, the state space does not necessarily have to be finite in a strict sense; it suffices when it is finitely representable. Remember that the state of the queue fluent (with an assumed length of 2) is given by a term of the form \( \text{list}(n_1, n_2) \), where the \( n_i \) can be any of the countably infinitely many standard names of sort object. For the purpose of verification, it however does not matter which requests the queue actually contains, but only how many, with only finitely many possible quantities. With the expressive power of first-order quantification, this simple form of abstraction can easily be achieved. In the example, the three abstract states of \text{queue} were

\[
(\text{Q1}) \text{ list}(e, e) \\
(\text{Q2}) \exists x_1. \text{ queue} = \text{list}(x_1, e) \\
(\text{Q3}) \exists x_1 \exists x_2. (x_1 \neq e) \land (x_2 \neq e) \land \text{queue} = \text{list}(x_1, x_2)
\]

where (Q1) was abbreviated as \( \text{Empty}(\text{queue}) \) and (Q3) as \( \text{Full}(\text{queue}) \). Had we propositionalized the theory using a fixed number of standard names as possible arguments in order to obtain finiteness, the state space would unnecessarily blow up exponentially. While it is easy to come up with an example where the algorithm does not terminate anymore, we believe that many practical applications share the properties of our example and that it therefore pays off to adopt the
Theorem 6 Let \( \alpha \) be a fluent formula. If the computation of \( \text{REGR}[\delta, \alpha] \) terminates, it is a fluent formula and 
\[
\Sigma \cup \Sigma_{\text{UNA}} \models (\delta)\alpha \iff \Sigma_0 \cup \Sigma_{\text{UNA}} \models \text{REGR}[\delta, \alpha].
\]
Again, convergence is only given when the set of possible traces is finitely representable by some formula. Let us illustrate the algorithm briefly. The most interesting case is how it works in the case of an iteration, therefore consider the simple program \( \delta = (\pi p.\text{requestCoffee}(p))^\ast \), which non-deterministically sends a finite number of coffee requests. The corresponding characteristic graph is depicted in Figure 2. Assume that we want to know whether there is some possible execution of this \( \delta \) such that the queue will be full afterwards, that is whether \( \Sigma \models (\delta)\text{Full(queue)} \). The set \( X \) gets initialized to \( \{\top \land \text{Full(queue)}\} \), which is equivalent to \( \{(Q3)\} \). Since the regression of \( (Q3) \) can be simplified to \( (Q2) \), we obtain \( \{(Q3), (Q2)\} \) in the first iteration of the algorithm and similarly \( \{(Q3), (Q2), (Q1)\} \) in the second one. The regression of \( (Q1) \) is equivalent to \( \bot \) and the algorithm converges; the resulting formula is the disjunction of \( (Q1)-(Q3) \), which is obviously entailed by \( \Sigma_0 \).

### Related Work

\( \mathcal{ESG} \) draws its inspiration from a number of other formalisms, most importantly dynamic logic (Harel, Kozen, & Tiuryn 2000), process logic (Harel, Kozen, & Parikh 1982; Harel, Kozen, & Tiuryn 2000), and temporal logics\(^3\) (Emerson 1990). Despite the commonalities, there are some differences. In particular, although there are first-order extensions of these logics, their expressiveness is often restricted. Atomic actions, for instance, are usually assumed to be assignments of the form \( x := t \), where \( x \) is a variable, and \( t \) is some term (Bohn et al. 1998). On the other hand, in the tradition of the situation calculus, \( \mathcal{ESG} \) allows to define pre- and postconditions of actions by arbitrary formulas.

There is a wide spectrum of ongoing research in the area of model-checking. The fundamental techniques for temporal logics, from which, in the case of \( \mathcal{CTL} \), our algorithm is clearly inspired, are discussed in (Clarke, Grumberg, & Peled 1999). Larger state spaces are tackled by resorting to symbolic model-checking, using an OBDD-based representation (Burch et al. 1990). Infinite state spaces are usually reduced to the finite case by means of predicate abstraction techniques (Chechik, Devereux, & Gurfinkel 2001; Bogunovi & Pek 2006). Many software model checkers are available, famous examples being NuSMV (Cimatti et al. 2002) and SPIN (Holzmnn 2003).

Regarding the verification of Golog programs, besides the work of (De Giacomo, Ternovska, & Reiter 1997) already discussed in the introduction, a model checker for non-terminating ConGolog programs using encodings in the \( \mu \)-calculus is reported in (Kalantari & Ternovska 2002). Liu (2002) presents a proof system in the style of Hoare logic for proving properties of terminating Golog programs. Kelly and Pearce (2007) present an algorithm for checking the persistence of formulas, which can be viewed as a special case of our method considering the fact that \( \square \alpha \) is equivalent to \( \neg(\langle \text{any} \rangle)^\ast \bigwedge \neg \alpha \). Verification of agent programs has naturally been studied for other action languages as well, e.g. in (de Boer et al. 2007), but is mostly limited to the propositional case.

### Conclusion

Based on an existing modal fragment of the situation calculus we proposed a new logic which allows us to formulate properties of non-terminating Golog programs in a natural way. In particular, we are able to express conditions that need to hold during the execution of a program, where these conditions may use operators known from branching-time logic. We further presented a method to automatically verify such conditions which uses ideas from model checking and regression-based reasoning. We adapted it to verify postconditions of terminating programs. We remark that, since (Lakemeyer & Levesque 2004) also provide a regression method for formulas containing \( \text{Know} \) operators, both the logic and all results presented in this paper can be extended to the epistemic case with few modifications. In the

---

\(^3\)Statements of temporal logics were first introduced into the situation calculus by (Gabaldon 2004), however only for finite sequences of actions.
future, we would like to explore verification methods for larger subclasses of the language.

Appendix: Characteristic Graphs

For a program $\delta$, the characteristic graph of $\delta$ is given by $G_\delta = (V, E, v_0)$, where

- $V$ is a finite set of vertices of the form $\langle \delta', \phi \rangle$, where $\delta'$ is a program and $\phi$ is a formula;
- $E$ is a finite set of edges of the form $v_1 \xrightarrow{\pi x/\psi} v_2$, where $v_1, v_2 \in V$ are nodes, $\pi x$ is a possibly empty list of variables, $t$ is a term of sort action and $\psi$ is a formula;
- $v_0 \in E$ is the initial node.

$G_\delta$ is defined by induction on the structure of $\delta$:

- $\delta = t$:
  
  $v_0 = \langle t, \bot \rangle$;
  
  $V = \{ \langle t, \bot \rangle, \langle \text{nil}, T \rangle \} \cup \{ \langle t, \bot \rangle \rightarrow \langle \text{nil}, T \rangle \}$.

- $\delta = \varphi$:
  
  $v_0 = \langle \text{nil}, \varphi \rangle$;
  
  $V = \{ \langle \text{nil}, \varphi \rangle \} \cup \{ \pi x \rightarrow \langle \text{nil}, \varphi \rangle \}$.

- $\delta = \delta_1 \delta_2$:
  
  Let $G_{\delta_1} = (V_1, E_1, v_{01})$ and $G_{\delta_2} = (V_2, E_2, v_{02})$, where $v_{01} = \langle \delta_1, v_0' \rangle$. Then
  
  $v_0 = \langle \delta_1, \delta_2, v_0' \wedge v_0'' \rangle$;
  
  $V = \{ \langle \delta_1, \delta_2, v_0' \wedge v_0'' \rangle \} \cup \{ \langle \delta_1', \delta_2', v_0' \wedge v_0'' \rangle \} \cup \{ \langle \delta_1, \delta_2', v_0' \wedge v_0'' \rangle \} \cup \{ \langle \delta_1', \delta_2, v_0' \wedge v_0'' \rangle \}$.

  $E = \{ \langle \delta_1, \delta_2, v_0' \wedge \delta_2', v_0'' \rangle \} \cup \{ \langle \delta_1', \delta_2, v_0' \wedge v_0'' \rangle \} \cup \{ \langle \delta_1, \delta_2', v_0' \wedge \delta_2', v_0'' \rangle \} \cup \{ \langle \delta_1', \delta_2', v_0' \wedge v_0'' \rangle \}$.

The idea here is to essentially leave $G_{\delta_1}$ as it is, but where each $\delta_1'$ turns into $\delta_1': \delta_2$ and each termination condition is augmented by $v_0''$, the condition under which $\delta_2$ is final.

$G_{\delta_2}$, then remains unchanged and we have copies of edges originally going out of $v_{01}'$ also at all $\delta_1': \delta_2$ nodes, with the additional constraint that $\delta_1'$ is final, i.e. that $\varphi_1'$ holds.

- $\delta = (\delta_1|\delta_2)$:
  
  Let $G_{\delta_1} = (V_1, E_1, v_{01})$ and $G_{\delta_2} = (V_2, E_2, v_{02})$, where $v_{01} = \langle \delta_1, v_0' \rangle$. Then
  
  $v_0 = \langle (\delta_1|\delta_2), v_0' \vee v_0'' \rangle$;
  
  $V = \{ v_0 \} \cup V_1 \cup V_2$;
  
  $E = \{ v_0 \xrightarrow{\pi x/\phi} v_i \mid \pi x \xrightarrow{\pi x/\phi} v_i \in E_1 \} \cup \{ v_0 \xrightarrow{\pi x/\phi} v_i \mid \pi x \xrightarrow{\pi x/\phi} v_i \in E_2 \}$.

Here we have a copy of each $G_{\delta_i}$. From the new initial node, there are copies of the outgoing edges of both $v_0'$. Thus, the first transition corresponds to the commitment to either $\delta_1$ or $\delta_2$, and all subsequent transitions have to be in the chosen subprogram.

- $\delta = \pi y.\delta_1$:
  
  Let $G_{\delta_0} = (V_1, E_1, v_{01})$, where $v_0 = \langle \delta_1, v_0'' \rangle$. Then
  
  $v_0 = \langle \pi y.\delta_1, \exists y. \psi \rangle$;
  
  $V = \{ v_0 \} \cup V_1$;
  
  $E = \{ v_0 \xrightarrow{\pi y.\delta_1, \phi} v_i \mid v_0 \xrightarrow{\pi y.\delta_1, \phi} v_i \in E_1 \} \cup E_1$.

In this case we extend a copy of $G_{\delta_0}$ with a new initial node whose outgoing edges contain the additional choice for $y$ and whose termination condition also requires the existence of an appropriate $y$.

- $\delta = (\delta_1|\delta_2)$:
  
  Let $G_{\delta_1} = (V_1, E_1, v_{01})$ and $G_{\delta_2} = (V_2, E_2, v_{02})$, where $v_0 = \langle \delta_1, v_0'' \rangle$. Then
  
  $v_0 = \langle (\delta_1|\delta_2), v_0' \wedge v_0'' \rangle$;
  
  $V = \{ \langle (\delta_1|\delta_2), v_0' \wedge v_0'' \rangle \} \cup \{ \langle \delta_1', \delta_2, v_0' \wedge v_0'' \rangle \} \cup \{ \langle \delta_1, \delta_2', v_0' \wedge v_0'' \rangle \}$.

  $E = \{ \langle \delta_1', \delta_2, v_0' \wedge \delta_2', v_0'' \rangle \} \cup \{ \langle \delta_1, \delta_2', v_0' \wedge \delta_2', v_0'' \rangle \} \cup \{ \langle \delta_1', \delta_2, v_0' \wedge v_0'' \rangle \} \cup \{ \langle \delta_1, \delta_2', v_0' \wedge v_0'' \rangle \}$.

The set of vertices here is something like the Cartesian product of the nodes of the $G_{\delta_i}$. Edges are such that either a transition in $\delta_1$ or one in $\delta_2$ is taken, and the other program remains unchanged.

- $\delta = (\delta_1)^*$:
  
  Let $G_{\delta_1} = (V_1, E_1, v_{01})$. Then
  
  $v_0 = \langle (\delta_1)^*, \top \rangle$;
  
  $V = \{ v_0 \} \cup \{ \langle \delta_1', (\delta_1)^*, v_1' \rangle \mid \langle \delta_1', v_1' \rangle \in V_1 \}$;
  
  $E = \{ v_0 \xrightarrow{\pi x/\phi} \langle \delta_1', (\delta_1)^*, v_1' \rangle \}$.

Here, we introduce a new initial node, which has $\top$ as the termination condition, and which has copies of the leaving edges of the initial node of $G_{\delta_1}$. The new $v_0$ furthermore has ingoing edges for each transition that leads to a node at which program execution may terminate.

To obtain simpler graphs, it is safe to drop any nodes and edges that are unreachable (in the graph theoretic sense) from $v_0$. In addition, we can identify both $\langle \text{nil}, \delta \rangle$ and $(\delta; \text{nil})$ with $\delta$, which further simplifies the resulting graph.

Appendix: Proofs

**Theorem 1** Let $\alpha$ be a sentence of $\mathcal{ES}$ without epistemic operators. Then $\models_{\mathcal{ES}} \alpha$ if and only if $\models_{\mathcal{E}\mathcal{S}^2} \alpha$. 

Proof: We show that for each α of classical EΣ, 

\( w, z, u \models_{EΣ} \alpha \iff w, z, u \models_{EΣ} \alpha \)

The claim is obvious for the cases \( H(t), V(t), (t_j = t_k) \), \( \alpha \land \beta, \neg \alpha, \forall v. \alpha, \) and \( \forall V. \alpha \) since their definition did not change. The cases \( \{ t \} \), \( \{ \} \), and \( \{ \} \) remain.

- For an atomic action term \( t \), the only possible transition step is \((t, z) \mapsto (n, z \cdot n)\), where \( n = |\{ t \}| \). Further \((n, z \cdot n) \in F^w,u \), therefore \( |\{ t \}| (z) = \{ n \} \). Then we have: \( w, z, u \models_{EΣ} \{ t \} \alpha \iff \alpha \).
- We have \((n, z \cdot n) \in F^w,u \), therefore \( |\{ t \}| (z) = \{ n \} \). Then we have: \( w, z, u \models_{EΣ} \{ t \} \alpha \iff \alpha \).

For any sequence \((\pi.a, z') \rightarrow (\pi, z \cdot n)\) for any sequence \(z'\) and any action name \( n\), therefore \((\pi.a)^w, z \cdot n \models_{EΣ} \alpha \).

Finally note that \((\pi.a, z') \rightarrow (\pi, z \cdot n)\) for any sequence \(z'\) and any action name \( n\), therefore \((\pi.a)^w, z \cdot n \models_{EΣ} \alpha \).

The following lemma, needed for the next theorem, gives a formal characterization of how characteristic graphs encode the transition relation and finality of program configurations:

Lemma 8 Let \( G_\delta = \langle V, E, v_0 \rangle \). Then

1. \( v_0 = \{ \delta, \phi \} \) for some \( \phi \).
2. \( \{ \delta, z' \} \mapsto \{ \delta', z' \} \iff \)

\( z' = n_0 \cdot n_{k-1} \) (\( k \geq 0 \)) and there are \( v_0, \ldots, v_k \in V \) and standard names \( \bar{n}_0, \ldots, \bar{n}_{k-1} \) such that

- \( v_i = \{ \delta_i, \phi_i \} \) for \( 1 \leq i \leq k \);
- \( v_i \mapsto v_{i+1} \) for \( 1 \leq i < k \);
- \( n_i = \{ (t_i)^{\bar{n}_{i-1}} \cdot \bar{n}_0 \} \) for \( 1 \leq i < k \);
- \( w, z, n_0 \cdot n_{k-1}, u \models (\psi_i)^{\bar{n}_{i-1}} \cdot \bar{n}_0 \) for \( 1 \leq i < k \);
- \( \delta' = (\delta_0)^{\bar{n}_{k-1}} \cdot \bar{n}_0 \).

3. \( \{ \delta, z \} \mapsto \{ \delta', z' \} \) and \( \{ \delta', z' \} \) in \( F^w,u \) iff the conditions listed in the previous item hold and additionally

\( w, z, z', u \models (\delta_0)^{\bar{n}_{k-1}} \cdot \bar{n}_0 \).

Proof: The first item can be shown by an induction on the structure of \( \delta \). Item 2 and 3 follow by an outer induction on \( \delta \) and an inner one on the length of the computation.
Theorem 5 Let $\varphi \in \mathcal{ESA}_{\mathcal{L}C}$. If the computation of $C[\varphi]$ wrt $\Sigma$ terminates, it is a fluent formula and

$$\Sigma \cup \Sigma_{\text{UNA}} \models \varphi \iff \Sigma_0 \cup \Sigma_{\text{UNA}} \models C[\varphi].$$

Proof: (Sketch) Let $w \models \Sigma$. We prove that $w, z \models \varphi$ iff $w, z \models C[\varphi]$ by induction on the structure of $\varphi$. It can also be proved that $C[\varphi]$ is a fluent formula, thus $w, \{ \varphi \} \models C[\varphi]$ iff $w' \models C[\varphi]$ for any $w'$ agreeing with $w$ on the fluents’ values in the initial situation, as defined by $\Sigma_0$.

The cases without $\langle \langle \delta \rangle \rangle$ quantifiers are easy. The intuition for the correctness of the other cases is the following. Let $w, z \models \langle \langle \delta \rangle \rangle X \varphi$ iff there is some first step $n$ in some execution trace of $\delta$ such that $w, z \cdot n \models \varphi'$; the latter by induction being the same as $w, z \cdot n \models C[\varphi]$. By Lemma 8, this holds iff $\mathcal{G}_\delta$ contains some edge, leaving $v_0$, and labelled $\pi_\varphi : t/\psi$, where $n$ is the denotation of $t^n_\varphi$ in $w, z \models \psi_{n_\varphi}$ for some $n$ and $w, z \cdot n \models C[\varphi]$. Using the correctness of regression from (Lakemeyer & Levesque 2004), Lemma 4, this is the same as when $w, z \models R[\varphi] \land [t[C[\varphi]], which is one of the disjuncts in $C[\langle \langle \delta \rangle \rangle X \varphi]$. $w, z \models \langle \langle \delta \rangle \rangle G \varphi$ iff $w, z \cdot z' \models \varphi$ (thus also $w, z \cdot z'' \models C[\varphi]$ by induction) for all prefixes $z'$ of some infinite execution trace $\pi$ of $\delta$. By Lemma 8, $z'$ corresponds to some path $t_1, \ldots, t_k \in \mathcal{G}_\delta$, starting in $v_0$. We can express that $C[\varphi]$ holds along this path by a fluent formula using regression:

$w, z \models C[\varphi] \land R[t_1, C[\varphi] \land R[t_2, C[\varphi] \land \ldots \land R[t_k, C[\varphi]] \ldots]]$

It is these formulas that CHECKEG computes iteratively in the set of labels, and when the procedure terminates, it means that the finitely many resulting disjuncts in $C[\langle \langle \delta \rangle \rangle G \varphi]$ suffice to capture all of them.

$w, z \models \langle \langle \delta \rangle \rangle \phi U \psi$ iff for some execution trace $\pi$ of $\delta$ and some prefix $z'$ of $\tau$, $w, z \cdot z' \models \psi$ and for all prefixes $z''$ of $z'$, $w, z \cdot z'' \models \phi$. The property can be expressed for $z'$ of length up to $k$, again using Lemma 8 and regression, as a formula of the form

$w, z \models C[\varphi] \lor C[\phi] \land R[t_1, C[\psi] \lor C[\phi] \land R[t_2, C[\psi] \lor \ldots \lor C[\phi] \land R[t_k, C[\psi]] \ldots]]$

which is basically what CHECKEU computes for increasing $k$ until convergence.
